1 INTRODUCTION

Machine Learning (ML) has lately become a prominent research area for the networking community, with applications in a broad range of topics such as traffic classification [17, 35], routing [11, 33], congestion control [5, 22], and traffic forecasting [21, 36]. In particular, in-network ML has become very attractive, as it allows to leverage the expressiveness of ML models at data plane speed [10, 31, 38]. The common denominator between many in-network ML use-cases is to train a model in the control plane using annotated historical data, and then deploy the model in the data plane for near real-time inference [10, 24, 29, 38]. Unfortunately, the training data will eventually become outdated (a phenomenon formally known as *"distribution shift"* or *"concept drift"*), causing the deployed ML model to suffer from performance degradation [18, 19]. While the necessity for frequent model updates has already been raised [6], three fundamental questions remain: (1) **When should we update our model?** The answer is (in theory) fairly simple: *continuously*. We should assume that the input patterns observed by a deployed ML model may change at any point in time; (2) **Which data should we select for model updates?** Again, the answer is (in theory) simple: *only the data that is useful for learning new things*. (3) **What should our model learn?** In principle, *everything*. We want a model that dynamically expands its predictive power without forgetting past experiences.

In this poster, we aim to take a step towards designing a solution that answers those questions. We propose combining Active Learning (AL) [26], which enables filtering relevant information from a vast pool of unannotated data, and Continual Learning (CL) [13], which allows us to learn from streaming data *without forgetting past concepts*. The former, implemented in the switch ASIC, allows us to choose *the right amount of information* that shall be mirrored to the control plane, where the model is updated continually. Finally, the new model can be installed back in the data plane.

Implementing this solution is nontrivial, and needs answering the following research questions: (1) how to implement AL-based filtering in the data plane?; (2) how selective should AL be for network learning?; (3) which ML models are most suitable for continual learning of network traffic?; and (4) how to dynamically reconfigure the data plane?

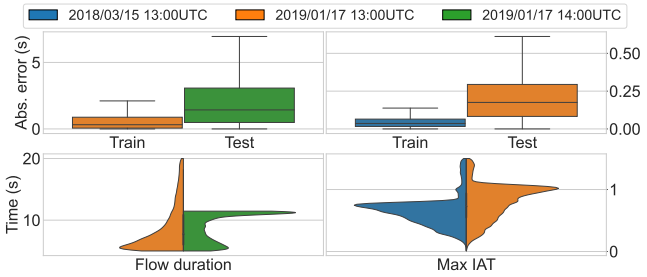

Figure 1: Distribution shift of TCP flow features from a real-world commercial backbone link [1]. The distribution shift of TCP features such as flow duration and inter-arrival time (IAT) causes performance degradation of a ML model trying to predict them.

2 THE CASE FOR CONTINUAL LEARNING

We run some tests on real-world traces to characterize the amount of distribution shift in TCP flow features. We extracted commonly-used features from real-world traces [1] (e.g., flow duration, inter-arrival time (IAT), and packet size statistics). We observed a shift in the flow duration and in the maximum IAT for small time scales (~one hour) and for large time scales (~a year), respectively. To quantify the impact of these shifts, we consider ad-hoc regression tasks[1] where the targets are either the flow duration or the maximum IAT. We observe[2] that the test error is significantly larger than training, a phenomenon that is imputable to the observed feature drifts (Fig. 1). Indeed, classical ML models will work properly only if the train and test data are approximately independent and identically distributed [8]. As such, practical in-network ML calls for smart, adaptive approaches.

Literature has been active in proposing *efficient means to offload ML schemes on the data plane* [10, 12, 31, 32, 39]. **Why can't we run existing proposals in a loop?** Pure Online Learning approaches 1) assume that every streamed data point is labeled, and 2) do not pay attention about forgetting as long as the model is fit to the current experience. In our proposal, we want not only to learn adaptively, but also to remember (and therefore exploit) everything that was observed in the past. In this way, *our model will not need additional data for re-learning already-observed concepts.*

[1]This is because CAIDA traces do not have task-specific class labels.
[2]For visualization purposes, we focus on the ranges [5, 20]s for flow duration and [0, 1.5]s for inter-arrival time.

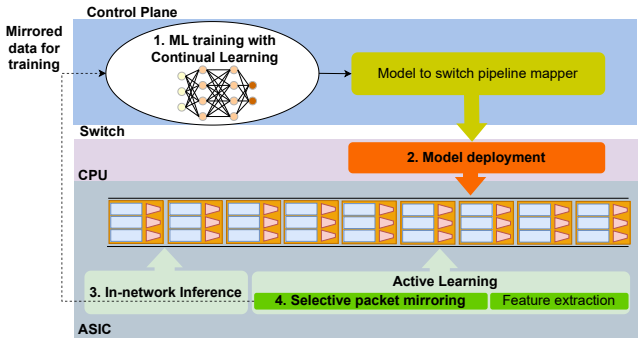

Figure 2: Our approach. The ML model is created (1) and then deployed in the switch ASIC (2), to perform inference at data plane speed (3). Selective mirroring (4) with Active Learning is deployed to keep the ML updated with Continual Learning.

3 OUR APPROACH

Fig. 2 illustrates our idea. We propose to incorporate in a single closed-loop framework the following building blocks:

(1) Model training: leveraging CL, the ML model updates and expands its knowledge over time.
(2) Model deployment: the trained ML model is deployed in the data plane (e.g., in a P4-compatible switch).
(3) In-network inference: the deployed ML model performs inference at data plane speed.
(4) Selective mirroring: leveraging AL, only the data useful for expanding the knowledge of the deployed model is mirrored to the control plane.

We seek to always run each component: while performing ML inference at data plane speed, our system learns continually by selecting only the most informative data.

As a proof-of-concept experiment, we consider a subset of the CIC2019 dataset for DDoS classification [27]. We consider DDoS classes to represent disjoint learning tasks, which are presented to the model in sequence. For each task, the model must not only discriminate between benign and malicious flows but also place the malicious flows in the right class.

We implement a baseline Continual Random Forest (CRF), consisting of a simple RF augmented with a replay buffer storing the most informative past exemplars. We use the vote count as AL query strategy, selecting only data points whose predictions had less than 90% majority. We retrain after each query, which is computationally very efficient for RFs. We consider Adaptive Random Forest (ARF) as a purely online (but not continual) baseline, which is among the state-of-the-art for Online Learning [14, 19]. In contrast to CRF, ARF assumes that every data point is labeled. We also consider an "oracle" RF trained on the full dataset as an upper-bound on the average performance over all learning tasks.

Fig. 3 shows the performance of CRF and ARF over the sequential tasks, and the percentage of queried labels by CRF

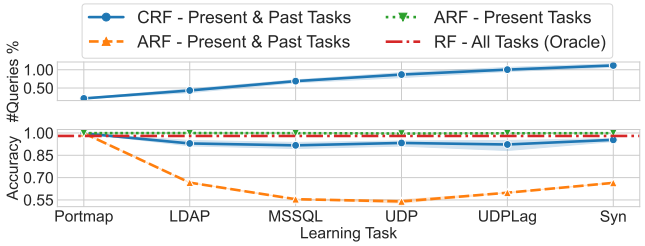

Figure 3: Adaptive vs. Continual Random Forests for class-incremental DDoS classification on CIC2019. At the end of the stream, CRF achieves performance close to an "oracle" while requiring only ~1% of the data.

relative to the full stream size. A purely adaptive learner such as ARF, though able to master individual tasks, quickly forgets past concepts. Instead, our baseline CRF achieves in the end a performance close to the oracle upper-bound, while requiring labeling only ~1% of the observed samples.

4 CHALLENGES

Challenge #1: implementing AL-based filtering in the data plane. While vote count in our baseline CRF is a decent query strategy, information-theoretic quantities [7, 15] are among the state-of-the-art. Their data plane implementation is not trivial, as it would require floating-point arithmetics. Even if not standard, authors in [20] propose a way to implement floating-point arithmetics in P4.

Challenge #2: how selective should AL be. A small selectivity implies a large mirroring overhead, whereas a large selectivity implies a potential information loss. Applying Active Learning to streaming data is, as of today, a novel twist on classical techniques [25]: investigating these trade-offs in a use-case basis opens up interesting research directions.

Challenge #3: choosing the right CL strategy. Our baseline leverages a slowly-growing experience buffer, which may not be desirable. Strategies for maintaining the buffer of fixed size can be investigated [23]. Other solutions, e.g., regularized neural networks, do not require any storage overhead other than the model [16], but are ill-advised for tabular data [28]. Ultimately, the choice depends on the available storage/computational resources and the goodness-of-fit to the characteristics of task-specific data.

Challenge #4: runtime dataplane reconfiguration. Currently, if want to add a new functionality to a switch, we need first to reroute the traffic of that switch, flush a new image in its ASIC and then restore the original traffic policy configuration. This process can lead to dramatic consequences if performed carelessly [2]. Programming the switch at run-time is possible [37], but not for RMT [9], the common commercial devices architecture [3, 4]. Researchers have also explored means to enable isolations between offloaded programs [30, 34, 40], which we will investigate to isolate the Active Learning processing and the rest of the pipeline.
